Summary

Mathematical modeling of healthcare-associated infection (HAI) epidemiology is a useful tool for addressing infections acquired during medical care, which cause significant morbidity, mortality, and financial strain on health systems worldwide. HAIs arise from complex interactions among patients, healthcare workers, the clinical environment, and microbial evolution. Because these interconnected processes are difficult to observe in real-world or experimental settings, models provide a powerful, risk-free way to understand how infections spread and how interventions may reduce transmission. We developed FacilityEpiSim, a continuous-time, agent-based simulation model of infectious disease transmission in healthcare facilities. The software tool allows modelers and their public health collaborators to run simulations to study transmission dynamics among facility patients and evaluate the utility of patient surveillance strategies before implementing them.

Statement of need

The tool is an agent-based model (ABM) built with Repast Symphony 2.11.0 (North et al. (2013)) for simulating transmission of an infectious organism in a healthcare facility. The model simulates flow of inpatients or residents of the facility over a specified time period, tracking patient admissions, lengths of stay, and discharges, disease importation and transmission dynamics, clinical detection and active surveillance testing with isolation of detected patients serving to partially decrease transmission. Patients in a susceptible state move to a colonized (i.e., infected) state at a rate proportional to the number of colonized patients currently in the facility, with detected colonized patients transmitting at a discounted rate according to the assumed isolation effectiveness. Undetected colonized patients can progress to clinical detection (i.e. a positive test driven by symptomatic, clinical infection) or can spontaneously return to a susceptible state upon decolonization.

The main intervention that can be tested in the simulation is active surveillance, which can occur at admission and/or at regular intervals during a patient's stay in the facility, with configurable adherence rates, test sensitivity, and durations between mid-stay tests. Active surveillance can identify asymptomatically colonized patients who would not otherwise have been detected and reduce transmission according to a configurable isolation effectiveness parameter.

These features fill a need to have realistic representation of patient flow, disease transmission, and interventions in a healthcare facility, so that researchers and public health strategists can disentangle alternate explanations of epidemiological data and anticipate the potential effects of interventions to mitigate facility outbreaks.

40 State of the field

41 While several open source software packages exist for general infectious disease outbreak
42 simulation (e.g., Jenness et al. (2013), Gozzi et al. (2025), Lorton et al. (2019), Grefenstette
43 et al. (2013), Gallagher et al. (2024), Meyer & Yon (2023)), none of these provide settings
44 specific to healthcare facility epidemiological scenarios without significant customization efforts
45 by the user. We found one public repository, H-outbreak, for spatial-temporal simulation for
46 hospital infection spread (Kim et al. (2023)), which emphasizes modeling spatial hospital
47 layout and staffing rather than transmission dynamics and surveillance.

48 We built FacilityEpiSim instead of extending existing projects because, to our knowledge,
49 all the above simulation models use discrete time steps rather than the continuous-time,
50 event-based framework implemented in our model. Using continuous time obviates the need
51 for choosing a time step frequency that could unintentionally affect simulation dynamics and
52 allows users to run a stochastic model that is directly analogous to deterministic differential
53 equation-based models that are commonly used in this field of mathematical modeling research.

54 Software design

55 We designed FacilityEpiSim to implement our simulation tool using an object-oriented
56 framework that anticipates potential future extensions to multiple facilities and multiple
57 diseases circulating simultaneously among the patient population. Multiple objects of classes
58 Person, PersonDisease, Facility and FacilityOutbreak and can be used to simulate and
59 study outbreaks in an agent-based simulation framework. The timing of events was designed
60 using the built-in event simulation capabilities of Repast. We designed customizable simulation
61 settings to match anticipated experimental use cases and also built R scripts designed to
62 analyze and display output for this purpose.

63 Research impact statement

64 A non open-source version of our code was used to generate results for three prior research
65 publications: Slayton et al. (2015), Toth et al. (2017), and Toth et al. (2020). These studies
66 demonstrated the utility of this simulation model for generating novel insights for public health.
67 With this open source version of our model, users can now configure simulation settings to
68 particular facilities, infectious organisms, and surveillance intervention strategies of interest
69 (Figure 1).

Figure 1: Parameters panel available when running the non-batch version of the simulation in Repast Simphony.

The code generates time series outputs, event logs for admissions, transmissions, detections, etc., and can also perform batch runs with parameter sweeps to test a range of assumptions or surveillance strategies. We also provide R scripts that analyze raw simulation output to verify model behaviors and view sensitivity analysis results. These capabilities will allow users to extend our prior, published research findings and generate new insights for public health.

AI Usage Disclosure

Generative AI was used in the creation of this project. Tools used include GitHub Copilot, Copilot Agents, and Claude Code. A variety of models were used with each tool, including Sonnet 4.5, Opus 4.5, GPT 4, GPT 5 and GPT-5 mini. These were used primarily in the creation of code and documentation. AI assisted in the generation of code, debugging, bootstrapping data analysis, scaffolding for documentation and some documentation generation. The authors of this paper assert that human authors reviewed, edited and validated all AI-assisted outputs and made the core design decisions.
