6 Summary

7 We introduce a Python open-source library for \mathcal{X} -armed bandit and online blackbox optimization
8 named PyXAB. PyXAB contains the implementations of more than 10 \mathcal{X} -armed bandit
9 algorithms, such as Zooming, StoS00, HCT, and the most recent works such as GP0 and
10 VHCT. PyXAB also provides the most commonly-used synthetic objectives to evaluate the
11 performance of different algorithms and the various choices of the hierarchical partitions on
12 the parameter space. The online documentation for PyXAB includes clear instructions for
13 installation, straightforward examples, detailed feature descriptions, and a complete reference
14 of the API. PyXAB is released under the MIT license in order to promote both academic and
15 industrial usage. The library can be directly installed from PyPI with its source code available
16 at <https://github.com/WilliamLwj/PyXAB>.

Statement of need

Online blackbox optimization has become a heated research topic due to the recent popularity of
machine learning models and thus the increasing demand for hyper-parameter tuning algorithms
([L. Li et al., 2018](#); [Shang et al., 2019](#)). Other applications, such as neural architecture search,
federated learning, and personal investment portfolio designs, also contribute to its prosperity
nowadays ([W. Li et al., 2022, 2023](#)). Different online blackbox optimization algorithms, e.g.,
Bayesian Optimization algorithms ([Shahriari et al., 2016](#)) and two-point evaluation methods
([Duchi et al., 2015](#); [Shamir, 2015](#)) have been proposed.

Apart from the aforementioned works, another very famous line of research is \mathcal{X} -armed bandit,
also known as Lipschitz bandit, global optimization or bandit-based blackbox optimization
([Bartlett et al., 2019](#); [Bubeck et al., 2011](#); [Grill et al., 2015](#); [Kleinberg et al., 2008](#)). In
this field, researchers split the parameter domain \mathcal{X} into smaller and smaller sub-domains
(commonly known as nodes) hierarchically, and treat each sub-domain to be an un-evaluated
arm as in the multi-armed bandit problems ([Azar et al., 2014](#); [Bubeck et al., 2011](#)). However,
such \mathcal{X} -armed bandit problems are much harder than their multi-armed counterparts, since
the number of sub-domains increases exponentially as the partition grows, and the hierarchical
structure/Lipschitzness assumption implies internal correlations between the “arms”. Therefore,
directly applying multi-armed bandit algorithms to such problems would be infeasible and more
complicated algorithms are developed ([Grill et al., 2015](#); [W. Li et al., 2023](#); [Shang et al., 2019](#)).

Despite the popularity of this area, most of the algorithms proposed by the researchers are either
not open-sourced or implemented in different programming languages in disjoint packages. For
example, StoS00 ([Valko et al., 2013](#)) is implemented in MATLAB and C¹, whereas H00 ([Bubeck](#)

Table 1: Selected examples of \mathcal{X} -armed bandit algorithms implemented in our library. *Cumulative*: whether the algorithm focuses on optimizing cumulative regret or simple regret. *Stochastic*: whether the algorithm deals with noisy rewards. *Open-sourced?*: the code availability before the development of PyXAB.

\mathcal{X} -Armed Bandit Algorithm	Cumulative	Stochastic	Open-sourced?
H00	yes	yes	yes (Python)
D00	no	no	no
StoS00	no	yes	yes (MATLAB, C)
HCT	yes	yes	no
P00	no	yes	yes (Python, R)
GPO	no	yes	no
Sequ00L	no	no	no
Stroqu00L	no	yes	no
VR00M	no	no	no
VHCT	yes	yes	no

et al., 2011) is implemented in Python². For most of the other algorithms, no open-sourced implementations could be found on the internet. We believe the lack of such resources results from the following two main reasons.

- The algorithms are long and intrinsically hard to implement due to the heavy usage of hierarchical partitions, node sampling, and the exploration-exploitation strategies that involve building, maintaining, and expanding complicated tree structures. It is hence time-consuming to implement and test one single algorithm.
- The problem settings for the algorithms could be slightly different. Some algorithms such as H00 (Bubeck et al., 2011) and HCT (Azar et al., 2014) are designed for the setting where the function evaluations can be noisy, while Sequ00L (Bartlett et al., 2019) is proposed for the noiseless case. Some algorithms focus on cumulative-regret optimization whereas some only care about the last-point regret or the simple regret³. Therefore, experimental comparisons often focus on a small subset of algorithms, see e.g., (Azar et al., 2014), (Bartlett et al., 2019). The unavailability of a general package only deteriorates the situation.

In Table 1, we provide the comparison among some of the algorithms implemented in PyXAB, including H00 (Bubeck et al., 2011), D00 (Munos, 2011), StoS00 (Valko et al., 2013), HCT (Azar et al., 2014), P00 (Grill et al., 2015) GPO (Shang et al., 2019), Sequ00L (Bartlett et al., 2019), Stroqu00L (Bartlett et al., 2019), VR00M (Ammar et al., 2020). and VHCT (W. Li et al., 2023).

To remove the barriers for future research in this area, we have developed PyXAB, a Python library of the existing popular \mathcal{X} -armed bandit algorithms. To the best of our knowledge, this is the first comprehensive library for \mathcal{X} -armed bandit, with clear documentations and user-friendly API references.

³A more detailed discussion on simple regret and cumulative regret can be found in [Bubeck2011X]

63 **Library Design and Usage**

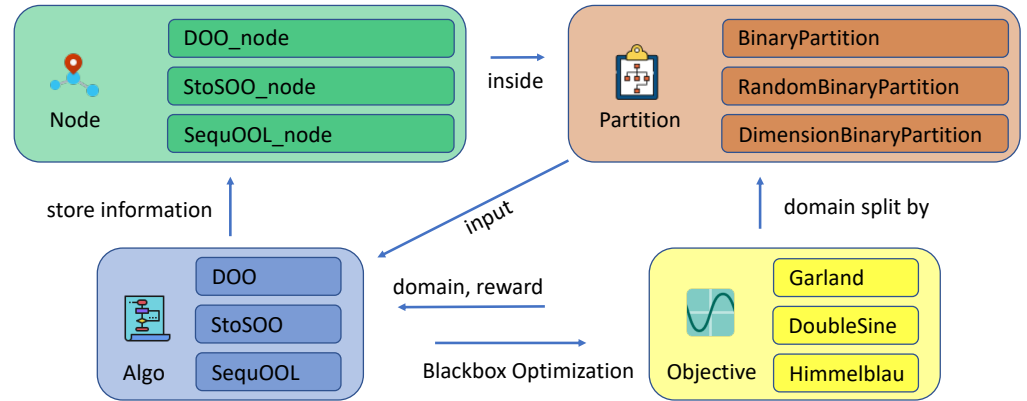

Figure 1: An overview of the PyXAB library structure.

64 The API of PyXAB is designed to follow the \mathcal{X} -armed bandit learning paradigm and to allow
 65 the maximum freedom of usage. We provide an overview of the library in Figure 1.

66 **Algorithm.** All the algorithms inherit the abstract class Algorithm. Each algorithm will
 67 implement two kinds of actions via: (1) a `pull()` function that returns the chosen point to be
 68 evaluated by the objective; (2) a `receive_reward()` function to collect the evaluation result
 69 and update the algorithm behavior.

70 **Partition.** Given any parameter domain, the user is able to choose any partition of the domain
 71 as part of the input of the optimization algorithm. All implemented partitions inherit the
 72 Partition class, which has useful base functions such as `deepen` and `get_node_list`. Each
 73 specific partition class needs to implement a unique `make_children()` function that split one
 74 parent node into the children nodes and maintain the tree structure. For implementation
 75 convenience, the package also provides a few built-in choices such as `BinaryPartition` and
 76 `RandomBinaryPartition`.

77 **Node.** The base node class used in any partition is `P_node`, which contains useful helper
 78 functions to store domain information and maintain the partition structure. However, we allow
 79 the algorithms to overwrite the node choices in any partition so that node-wise operations
 80 are allowed. For example, the `StoS00` algorithm needs to compute and store the $b_{n,i}$ -value for
 81 each node (Valko et al., 2013). The `Stroqu00L` algorithm needs to record the number of times
 82 a node is opened (Bartlett et al., 2019). Therefore, different node classes are implemented for
 83 these algorithms.

84 **Objective.** For all the objectives implemented in this package, they all inherit the `Objective`
 85 class and all have a function `f()` that returns the evaluation result of a given point. We also
 86 provide the commonly used synthetic objectives which are used to evaluate the performance of
 87 \mathcal{X} -armed bandit algorithms in research papers, such as `Garland`, `DoubleSine`, and `Himmelblau`.

88 The usage of the PyXAB library is rather straightforward. Given the number of rounds, the
 89 objective function, and the parameter domain, the learner would choose the partition of the
 90 parameter space and the bandit algorithm. Then in each round, the learner obtains one point
 91 from the algorithm, evaluate it on the objective, and return the reward to the algorithm. The
 92 following snippet of code provides an example of optimizing the `Garland` synthetic objective on
 93 the domain `[[0, 1]]` by running the `HCT` algorithm with `BinaryPartition` for 1000 iterations.
 94 As can be observed, only about ten lines of code are needed for the optimization process apart
 95 from the import statements.

```
from PyXAB.synthetic_obj.Garland import Garland
from PyXAB.algos.HCT import HCT

# Define the number of rounds, target, domain, and algorithm
T = 1000
target = Garland()
domain = [[0, 1]]
algo = HCT(domain=domain)

# Run the algorithm HCT
for t in range(1, T+1):
    point = algo.pull(t)
    reward = target.f(point)
    algo.receive_reward(t, reward)
```

Code Quality and Documentations

In order to ensure high code quality, we follow the PEP8 style and format all of our code using the black package⁴. We use the pytest package to test our implementations with different corner cases. More than 99% of our code is covered by the tests and Github workflows automatically generate a coverage report upon each push or pull request on the main branch⁵.

We provide detailed API documentations for each of the implemented classes and functions through numpy docstrings. The documentation is fully available online on ReadTheDocs⁶. On the same website, we also provide installation guides, algorithm introductions, both elementary and advanced examples of using our package, as well as detailed contributing instructions and new feature implementation examples to encourage future contributions.
